

Annexe X

Distributions de contrôle – $H \rightarrow \tau\tau$

Cette annexe présente des distributions de contrôle avant ajustement des paramètres de nuisance sur les événements utilisés dans l’analyse des événements $H \rightarrow \tau\tau$ présentée dans le chapitre 4. La sélection est « inclusive », les événements sont ceux sélectionnés par la définition de la région de signal, sans coupure sur m_T^ℓ (canaux $\mu\tau_h, e\tau_h$) ni D_ζ (canal $e\mu$).

Pour chacune des trois années de prise de données (2016, 2017, 2018) et chacun des quatre canaux ($\tau_h\tau_h, \mu\tau_h, e\tau_h, e\mu$), les distributions de plusieurs variables sont données.

Dans chacun des graphiques, les données observées (points noirs) sont comparées à la modélisation des bruits de fond (histogrammes remplis en couleur et empilés). Les bandes grisées correspondent à l’incertitude statistique totale sur le bruit de fond. Le rapport au bruit de fond est donné dans la partie inférieure des graphiques.

Ces distributions montrent un bon accord entre données observées et estimations des bruits de fond, à l’exception :

- des pseudo-rapidités des τ_h , $\eta(\tau_h)$;
- du nombre de vertex d’empilement N_{PU} .

Les membres du groupe de l’analyse MSSM $H/A \rightarrow \tau\tau$ ont récemment été mis au courant des écarts observés et de plus amples investigations sont prévues. Ci-après, les pistes envisagées sont présentées.

Pseudo-rapidités des τ_h L’écart observé pourrait être réduit en utilisant des facteurs de faux dépendants de $\eta(\tau_h)$, ce qui n’est pas le cas actuellement. D’autres variables dépendant directement de la pseudo-rapidité d’un τ_h telles que la distance ΔR entre les deux éléments du dilepton montrent également des écarts entre données observées et estimation des bruits de fond, potentiellement dus à ceux sur $\eta(\tau_h)$. L’effet attendu sur la variable discriminante m_T^{tot} est faible, cette dernière étant fonction d’impulsions transverses et d’angles azimutaux. Une étude plus approfondie sur la corrélation de m_T^{tot} avec $\eta(\tau_h)$ ainsi que l’effet de l’utilisation de facteurs de faux dépendants de $\eta(\tau_h)$ sur les distributions de m_T^{tot} permettrait de quantifier cet effet.

Nombre de vertex d’empilement L’effet de la mauvaise modélisation de N_{PU} constatée dans les distributions de contrôle devrait être marginal sur m_T^{tot} , car cette observable ne dépend pas de N_{PU} . Les autres sources d’incertitudes sur m_T^{tot} permettent alors de couvrir cet effet. Les valeurs de m_{ML} , c’est-à-dire des prédictions du réseau de neurones présenté au chapitre 5, dépendent de N_{PU} . Les bons accords entre observations et estimations des bruits de fond obtenus sur les distributions de m_{ML} montrent que cette observable semble peu affectée par la mauvaise modélisation de N_{PU} . Ainsi, l’effet limité de N_{PU} sur les variables discriminantes utilisées permet de conserver des résultats finaux pertinent bien que l’écart sur N_{PU} entre observations et estimations des bruits de fond puisse être de l’ordre de 40 %. Plusieurs effets peuvent causer un tel écart sur les distributions de N_{PU} :

Modélisation des chemins de déclenchement dans les données encapsulées Les données encapsulées, introduites dans le chapitre 4, sont des hybrides entre données réelles et simulées. Les chemins de déclenchement activés proviennent de la partie simulée uniquement, c’est-à-dire d’un événement vide à l’exception des leptons τ qui remplacent les muons. Or, l’empilement provient de

la partie réelle des données encapsulées et l'acceptation des chemins de déclenchement en dépend. Actuellement, des facteurs correctifs sont appliqués en fonction des propriétés cinématiques des τ mais ils ne dépendent pas de N_{PU} . Ainsi, les distributions de N_{PU} peuvent être biaisées dans les données encapsulées.

Dépendance en N_{PU} de l'identification des τ_h L'identification d'un τ_h dépend de son isolation, elle-même sensible à l'empilement. Différents points de fonctionnement d'identification des τ_h sont utilisés dans le cadre des facteurs de faux, introduits au chapitre 4. Ces derniers ne sont pas déterminés en fonction de N_{PU} , ce qui peut introduire un biais.

Modélisation de N_{PU} dans les données simulées Un désaccord sur N_{PU} est bien attendu entre données réelles et simulées et ces dernières sont pondérées afin de le corriger, comme exposé au chapitre 2. Toutefois, cette pondération ne permet pas d'obtenir un accord parfait.
